ABSTRACT: We present here a detailed molecular-level understanding of the interactions among surface-functionalized mesoporous SBA-15 silica and pharmaceutical guests that influence macroscopic adsorption and release behaviors. A model drug species, methylprednisolone sodium succinate, was adsorbed on the surfaces of functionalized mesoporous SBA-15 silica materials with different aminooalkyl species and without or with C60 fullerene moieties. Zeta potential measurements show that the electrostatic interactions among methylprednisolone species and modified silica surfaces are important for the adsorption and release of the methylprednisolone molecules. Complementary one and two-dimensional (2D) solid-state 13C{1H} NMR measurements provide evidence for specific intermolecular interactions between adsorbed methylprednisolone species and different types of functionalized silica surfaces. In particular, correlated 13C and 1H signal intensities from the methylprednisolone alkyl moieties and the aminoalkyl groups of the functionalized silica surfaces unambiguously establish their close (<1 nm) molecular proximities and strong interactions. The molecular-level insights are correlated with macroscopic adsorption and release behaviors of methylprednisolone, providing detailed new understanding of the interactions responsible for the high loadings and slow release of this important pharmaceutical agent from surface-functionalized mesoporous materials.

INTRODUCTION

The biocompatibilities, robustness, high specific surface areas, and facile surface functionalization of mesoporous silicas make these materials promising for applications in drug delivery.†‡ Drug delivery systems (DDSs) aim to improve therapeutic efficacies and prevent the overdoses of pharmaceutical species by providing site-specific delivery of pharmaceuticals at controlled rates within the body. An additional objective for DDSs is to increase patient compliance by reducing the frequency of doses during the course of treatment, which is achieved by extending the duration over which DDSs deliver effective quantities of pharmaceuticals. Consequently, DDSs are engineered to maximize the adsorption capacities and control the release of pharmaceutical species under biological conditions (e.g., in the bloodstream, sinuses, etc.). Mesoporous silicas are promising as DDSs, because their high surface areas enable large pharmaceutical adsorption capacities and the robust silica frameworks render chemical and mechanical stability under biological conditions. By comparison, the relatively large (2–30 nm) pore sizes of mesoporous silicas allow pharmaceutical guests of large sizes to access the interior mesoporous surfaces. Furthermore, both the internal mesochannel and external particle surfaces of mesoporous silicas can be functionalized with a variety of pharmaceutically inactive chemical moieties that interact with molecular guests and thereby influence the adsorption and release properties of guest species.†‡§ Combined with the large pores, high surface areas and biocompatibilities, the ability to easily adjust material properties by surface functionalization enables mesoporous silicas to be highly effective DDSs for a variety of chemically distinct pharmaceuticals.

Functionalities at mesoporous silica surfaces can promote the adsorption of molecular guests to enable a variety of technological applications and are especially relevant in mesoporous silica-based drug delivery systems. In most cases, the adsorption of molecular guests to mesoporous silica surfaces involves hydrophobic, hydrogen-bonding, electrostatic, or covalent interactions among the guests and moieties at the silica surface. The strengths and extents of these distinct intermolecular interactions depend on the types and compositions of the surface functional groups, which significantly influence the chemical activities, acid–base properties, and hydrophobicities of mesoporous silicas. For example, mesoporous silica grafted with alkyl, haloalkyl, or aryl moieties exhibit increased surface hydrophobicity compared to nonfunctionalized mesoporous silica.

hydrophobic materials enable enhanced chromatographic performance when used as the stationary phase in reverse-phase high performance liquid chromatography columns, relative to commonly used silica gels.\textsuperscript{19} By comparison, hydrophilic nonfunctionalized mesoporous SBA-15 silicas have high concentrations of surface silanol groups that interact with ibuprofen species by hydrogen-bonding, enabling high quantities of these pharmaceutical molecules to be adsorbed to such nonfunctionalized mesoporous silica surfaces.\textsuperscript{20} Covalent interactions also result in the strong adsorption of guest molecules to functionalized mesoporous silicas and can facilitate the capture of dilute radionuclide,\textsuperscript{21} boron,\textsuperscript{22} or fullerene\textsuperscript{3,23} species from solution by functionalized mesoporous materials. Molecular adsorption can also be influenced by electrostatic interactions, which enable the high adsorption capacities of poorly water-soluble prednisolone species to polyethyleneimine-functionalized mesoporous silica materials.\textsuperscript{24}

The release rates of pharmaceutical guests from mesoporous silica materials are strongly influenced by adsorption behaviors of the guest species near surface functional groups, which are mediated by site-specific molecular interactions. Specifically, slower transport of molecular species within silica mesochannels can result from adsorption interactions and steric effects between the guest species and surface moieties. Moreover, molecular release rates can also be influenced by the hydrophobicities of the mesoporous materials, which determine the rates at which aqueous biological media (e.g., blood) partition into materials and subsequently solubilize molecular guests. As a result, several previous studies have relied on modifying mesoporous materials with hydrophobic and/or bulky surface groups to control molecular release. Mesoporous SBA-15 silica materials functionalized with octyl or octadecyl groups exhibit erythromycin release rates that are 1 order of magnitude lower than from mesoporous silicas without surface functionalization.\textsuperscript{25} Similarly, slow release rates have been reported for captopril\textsuperscript{26} and ibuprofen\textsuperscript{27} from mesoporous silicas with high degrees of surface silylation, which yields high surface hydrophobicities and correspondingly strong adsorption of pharmaceutical guests. Molecular simulations by Vallet-Regi and co-workers have suggested that a combination of electrostatic and hydrogen-bonding interactions are responsible for drug adsorption, desorption, and diffusion behaviors of pharmaceutical guests within surface-functionalized mesoporous silica hosts.\textsuperscript{28,29} However, until now, direct molecular-level experimental measurements of such interactions and properties have been limited or absent.

The objective of this investigation is to understand the molecular interactions that mediate the adsorption and desorption of the pharmaceutical species methylprednisolone from the functionalized surfaces of mesoporous SBA-15 silicas to establish design criteria for controlled release applications. The incorporation of C$_{60}$ into mesoporous silica materials is expected to yield a combination of hydrophobic, \textpi–\textpi, and steric interactions that enable high methylprednisolone adsorption capacities and reduced rates of macroscopic release. Functionalization of similar mesoporous MCM-41 materials with fullerene C$_{60}$ species has been achieved by covalently attaching C$_{60}$ species to grafted amino organosilica groups;\textsuperscript{30} however, the resulting materials were not evaluated for the adsorption and release of pharmaceutical guests. Corticoids, including a variety that are synthetically manufactured, are commonly used for medicinal purposes because of their broad relevance in physiological processes, including regulation of stress and immune responses, inflammation, carbohydrate metabolism, protein catabolism, and blood electrolyte levels. The synthetic corticoid methylprednisolone was chosen as a representative pharmaceutical guest for this study, because it is often prescribed to treat a number of different health conditions including arthritis, sinusitis, bronchitis, and cancer.

The molecular interactions among adsorbed methylprednisolone guests and fullerene (e.g., C$_{60}$) functional groups at the mesoporous silica surfaces are established and correlated with methylprednisolone adsorption and release at the macroscopic level. The quantities of amino organosilica, HC$_{60}$, and methylprednisolone species incorporated into mesoporous SBA-15 silica hosts are established by using solid-state NMR spectroscopy, elemental analysis, and thermogravimetry, while the textural properties (i.e., surface areas, pore sizes, etc.) of materials were obtained from N$_{2}$ adsorption analyses. Zeta potential values for bulk functionalized materials indicate electrostatic interactions among methylprednisolone guests and the silica surface, the magnitudes of which correlate qualitatively with methylprednisolone adsorption capacities. Moreover, hydrogen-bonding and hydrophobic interactions of adsorbed methylprednisolone species with groups at the mesoporous silica surface are manifested directly by one- and two-dimensional solid-state $^{13}$C{\text{1H}} NMR spectroscopy. Insights regarding these intermolecular interactions are correlated with and explain the macroscopic release rates of methylprednisolone from functionalized mesoporous silica hosts into simulated body fluids at neutral and acidic conditions, which correspond to biological environments of the bloodstream and proximate to tumors, respectively. The surface-functionalized mesoporous SBA-15 silica materials in this study show higher methylprednisolone adsorption capacities and exhibit substantially longer release times compared to other nonfunctionalized mesoporous silicas and zeolite materials.\textsuperscript{31} This detailed understanding of C$_{60}$-functionalized mesoporous silica loaded with methylprednisolone guests at molecular and macroscopic levels provides new opportunities for designing mesoporous silica-based materials for controlled pharmaceutical release.

\begin{itemize}
  \item EXPERIMENTAL SECTION
\end{itemize}

\textbf{Materials. Synthesis of SBA-15-NH$_{2}$ Silica.} The synthesis of mesoporous SBA-15 silica materials was accomplished using the method described previously by Zhao et al.\textsuperscript{32} Mesoporous SBA-15 silica materials functionalized with organosilica species were synthesized as follows: 2.0 g of calcined SBA-15 silica was held under vacuum (200 mbar) at a temperature of 150 °C overnight to eliminate residual water. Next, these materials were added to 250 mL of anhydrous toluene stored under a nitrogen atmosphere and the mixture was stirred for 30 min at 110 °C. Then, 5.6 mmol of an organosilica precursor, specifically 3-aminopropyl trimethoxysilane (APS) or 4-amino-butyl trimethoxysilane (ABS), was added to this mixture, and the resulting mixture was stirred at 110 °C for 24 h. The solids were washed twice with toluene and acetone, filtered, and then dried overnight under vacuum (200 mbar). SBA-15 silica materials with grafted amino organosilica species are collectively referred to as SBA-15-APS-NH$_{2}$, or as SBA-15-APS-NH$_{2}$ and SBA-15-ABS-NH$_{2}$ to reflect the type of organosilica incorporated.

\textbf{Preparation of SBA-15-NH$_{2}$-C$_{60}$H Materials.} A solution containing fulleride anion [C$_{60}$]$^{-}$ was prepared by mixing C$_{60}$ fullerene (86 mg, 0.12 mmol) with tetrahexylammonium bromide (THAB, 261 mg, 0.60 mmol) in 32 mL of anhydrous...
tetrahydrofuran (THF) and 2−3 drops of mercury. The mixture was heated and maintained at 80 °C in a nitrogen atmosphere for 3 h after which the solution became dark red in color, which is the characteristic color of C_{60} radical ions. Subsequently, 400 mg of SBA-15-NH$_2$ was added to the solution containing C_{60} radical ions and the mixture stirred for 20 h under a nitrogen atmosphere. The solids were then filtered, washed twice with toluene and acetone to remove unreacted C$_{60}$ radical ions and THAB. Finally, these materials were dried under vacuum at 70 °C overnight. As the color, which is the characteristic color of C$_{60}$ radical ions, was obtained using a Micromeritics TRISTAR 3000 porosimeter. Prior to measurement, mesoporous SBA-15 silica materials were outgassed under vacuum at 300 °C, while materials with incorporated amino organosilica or C$_{60}$ fullerene species were outgassed at 100 °C under vacuum. The adsorption−desorption isotherm measurements were performed according to the B.E.T. method using nitrogen adsorption points in the range P/P$_0$ = 0.05−0.2. Pore size distributions were determined by applying the Barret−Joyner−Halenda model (B.J.H.) to the adsorption branch of the

Scheme 1. Principal Steps and Intermediates Involved in the Preparation of SBA-15-NH-HC$_{60}$ Materials$^a$

“Fulleride [C$_{60}$]$^-\$ anions are formed as a product by mixing C$_{60}$ fullerene species with THF in the presence of THAB and Hg (left arrow). This solution is exposed to the SBA-15-NH$_2$ materials (right arrow), which results in the covalent attachment of fulleride species to the primary amine groups of the amino organosilica species to yield SBA-15-NH-HC$_{60}$ materials.

Sterilized dialysis bags (molecular-weight cutoff 10 000 Da) were pretreated prior to use by immersion into a boiling aqueous mixture of 50% ethanol (v/v) for 1 h. Then the dialysis bags were washed with water up to 40 °C for 1 h and then immersed in a simulated body fluid (SBF) at 37 °C for 2 h. For pharmaceutical release experiments at neutral conditions the SBF consisted of a phosphate buffered saline (PBS) solution (pH 7.4), while an acetate buffered solution (pH 4.6) was used for experiments under acidic conditions.

Methylprednisolone release from materials into SBF was monitored to understand pharmaceutical release properties of these materials. SBA-15, SBA-15-NH$_2$, or SBA-15-NH-C$_{60}$H material (100 mg) loaded with methylprednisolone species was dispersed into 2 mL of SBF. This suspension was subsequently added to a pretreated dialysis bag, which was sealed and placed into bottles containing 100 mL of SBF (referred to as release media). Bottles were shaken at 100 rpm at 37 °C. At designated time points, every 15 min for the first 2 h, 1 h for the next 8 h, and 3 h until the released drug concentration remained constant, 1 mL of the SBF release media was withdrawn and a UV−vis absorption spectrum of this sample was collected, using neat SBF as baseline absorption. The 1 mL of the SBF sample was then returned to the original SBF release media directly after the UV−vis measurement. The concentration of methylprednisolone species in the SBF release media was calculated by using the Beer−Lambert law to its UV absorbance intensity at 248 nm, an adsorption wavelength associated with methylprednisolone species, using an extinction coefficient of 12 400 M$^{-1}$ cm$^{-1}$. Exposure of surface-functionalized silica materials to an additional 100 mL of methylprednisolone-free simulated body fluid resulted in the release of more methylprednisolone, suggesting that its release from these materials may be limited by adsorption/desorption equilibrium under the conditions used.

Characterization. Small-angle X-ray diffraction (XRD) measurements enable characterization of mesoscopic ordering in SBA-15 derived silica materials and were obtained with a Philips XPERT MPD diffractometer using Cu Kα radiation. The textural properties of the mesoporous silica materials were established by analysis of nitrogen adsorption−desorption isotherms at −196 °C obtained using a Micromeritics TRISTAR 3000 porosimeter. Prior to measurement, mesoporous SBA-15 silica materials were outgassed under vacuum at 300 °C, while materials with incorporated amino organosilica or C$_{60}$ fullerene species were outgassed at 100 °C under vacuum. The adsorption−desorption isotherm measurements were performed according to the B.E.T. method using nitrogen adsorption points in the range P/P$_0$ = 0.05−0.2. Pore size distributions were determined by applying the Barret−Joyner−Halenda model (B.J.H.) to the adsorption branch of the
isotherm assuming a cylindrical pore geometry. For each sample, the average pore diameter was estimated as the value associated with the maximum intensity of the pore size distribution curve. Total pore volume was calculated at a relative pressure $P/P_0$ of 0.985.

NMR measurements conducted at Rey-Juan Carlos University, including one-dimensional (1D) solid-state $^{13}$C($^1$H) cross-polarization magic-angle-spinning (CP-MAS) and single-pulse $^{29}$Si MAS NMR experiments, were performed on a Varian Infinity 400 MHz spectrometer fitted with a 9.4 T magnetic field. At this field strength, the $^{13}$C and $^{29}$Si nuclei Larmor frequencies are 100.53 and 79.41 MHz, respectively. Samples were packed in 7.5 mm zirconia rotors and experiments were conducted at room temperature under MAS conditions of 6 kHz using an H/X double-resonance 7.5 mm MAS probehead.

Solid-state 1D and two-dimensional (2D) $^1$H and $^{13}$C NMR measurements were carried out on mesoporous SBA-15-APS-$^{15}$N-$^{15}$O-H silica samples without and with methylprednisolone guest species to understand intermolecular interactions among the guest species, organic surface moieties, and silica walls. Approximately 80 mg of sample was loaded into 4 mm zirconia MAS rotors for solid-state 1D and 2D NMR measurements. Solid-state 1D $^{13}$C($^1$H) CP measurements were conducted by a 4 mm double-resonance variable-temperature Bruker MAS probehead at 11.7 T using a Bruker AVANCE II spectrometer with operating frequencies of 500.24 MHz for $^1$H and 125.79 MHz for $^{13}$C. Cross-polarization was used to transfer magnetization from $^1$H to $^{13}$C nuclei by adiabatic passage according to the Hartmann–Hahn condition. Solid-state 1D $^{13}$C($^1$H) CP measurements were conducted at room temperature under 12.5 kHz MAS conditions with a 2 ms CP contact time, recycle delay of 1 s, 10 000 transients, and with SPINAL-64 heteronuclear $^1$H decoupling.

Solid-state 2D $^{13}$C($^1$H) heteronuclear correlation (HETCOR) measurements were conducted using a 4 mm triple-resonance Bruker MAS probehead using a Bruker ASCEND-III NMR spectrometer at 9.4 T with operating frequencies of 400.02 MHz for $^1$H and 100.64 MHz for $^{13}$C. The 2D $^{13}$C($^1$H) HETCOR spectrum was acquired under 10 kHz MAS conditions, using a 2 ms CP contact time and 5 s recycle delay with 12 $t_1$ increments at an incremental size of 96 $\mu$s and 3072 transients each. Quadrature detection in the indirect ($^1$H) dimension was achieved using time-proportional phase-incrementation. High power (100 kHz) $^1$H–$^1$H homonuclear decoupling using the eDUMBO-1$_{22}$ sequence was applied during the $^1$H $t_1$ evolution period to enhance resolution in the $^1$H dimension. For the indirect dimension, a scaling factor of 0.60 was calibrated from a separate 2D $^{13}$C($^1$H) NMR spectrum of 99% $^{13}$C- and $^{15}$N-enriched glycine sample conducted under identical experimental conditions. During signal acquisition, heteronuclear $^1$H decoupling was achieved using a SPINAL-64 pulse sequence at a $^1$H nutation frequency of 100 kHz. Separate 1D $^{13}$C($^1$H) CP-MAS and single-pulse $^1$H spectra are shown at the top and alongside the 2D spectrum, respectively, and were acquired under identical experimental conditions as those of the associated 2D. Contour levels in the 2D spectra correspond to 5, 15, 25, 40, 55, and 75% of the maximum signal intensity. $^1$H and $^{13}$C chemical shifts in all 1D and 2D measurements were referenced to neat tetramethylsilane (TMS, 0 ppm), using tetramethylsilane as an external secondary reference (with $^{13}$C and $^1$H chemical shifts of 3.52 and 0.25 ppm relative to TMS, respectively).

Amino organosilica and pharmaceutical guest loadings were determined by thermogravimetric analysis (TGA) with a Star System Mettler Thermobalance and separately, elemental microanalyses with a Vario EL III apparatus. Zeta potentials were calculated based on measurements of the electrophoretic mobilities of bulk mesoporous materials using a zeta potential analyzer (Zetasizer Nano ZS, Iesmat).

### RESULTS AND DISCUSSION

The quantities of aminopropyl organosilica species grafted to the silica surface of SBA-15-APS silica and adsorption properties of these materials are obtained from elemental analyses, TGA, solid-state NMR spectroscopy, and $N_2$ adsorption measurements. The carbon contents of SBA-15-APS materials can be directly related to the amounts of grafted organosilica species and establish aminopropyl organosilica loadings of 1.6 mmol per gram of SBA-15-APS material. Corroborative evidence for these organosilica loadings is provided by 1D single-pulse $^{29}$Si NMR (Figure S1) and TGA (Figure S2) data, which indicate organosilica loadings of 1.0 and 1.1 mmol per gram of SBA-15-APS materials, respectively. Analyses of $N_2$ adsorption data reveal significantly reduced BET surfaces areas (Table 1) for SBA-15-APS ($391 \text{ m}^2 \text{ g}^{-1}$ material) with respect to SBA-15 silica ($582 \text{ m}^2 \text{ g}^{-1}$ material), which results, in part, from the added mass associated with grafted aminopropyl organosilica species. Normalizing the specific surface area to the mass of silica framework in SBA-
15-APS materials provides an adjusted surface area of 455 m² g⁻¹ silica, reflecting that grafted aminopropyl organosilica species block mesopores and/or prevent N₂ adsorption to the silica surface. However, pore blockage by incorporated organosilica species is unlikely, based on the highly similar pore volumes of SBA-15-APS materials (0.85 cm³ g⁻¹ silica) and mesoporous SBA-15 silica (0.78 cm³ g⁻¹ silica). These results establish that the surface areas of SBA-15-APS materials are similar to those of mesoporous SBA-15 silica materials, though are somewhat reduced by the presence of the grafted aminopropyl organosilica species. Interestingly, the average pore diameter of SBA-15-APS silica is nearly identical to that of mesoporous SBA-15 silica (Table 1). The high quantities of incorporated aminopropyl organosilica species, minimal pore blockage, and mesochannel pore sizes of SBA-15-APS materials are expected to enable incorporation of relatively high amounts of C₆₀ species.

The quantities of C₆₀ incorporation and N₂ adsorption properties of SBA-15-APS-C₆₀H materials are established by elemental analysis, TGA, solid-state NMR spectroscopy, and N₂ adsorption. A comparison of the carbon contents of SBA-15-APS materials without and with HC₆₀ species establishes C₆₀ loadings of 0.17 mmol per gram of SBA-15-APS-C₆₀H material, which is in agreement with the 0.26 mmol C₆₀ per gram obtained by analyses of TGA data (Table S1). Importantly, these incorporated C₆₀ species appear to be covalently attached to aminopropyl organosilica species based on solid-state 1D ¹³C{¹H} CP-MAS NMR spectra (Figure 1A) of SBA-15-APS-C₆₀H materials, which show a broad (full-width half-height of 10 ppm) ¹³C signal at 135–155 ppm assignable to C₆₀ moieties (Figure 1A, blue dot). A similarly broad ¹³C NMR signal was attributed C₆₀ species covalently bound to surface aminopropyl moieties in mesoporous MCM-41 silica, while sharp signals were observed for nonattached and mobile C₆₀ species. Therefore, the 1D NMR analysis provides strong evidence that C₆₀ species incorporated into SBA-15-APS-C₆₀H materials are, in fact, attached to surface aminopropyl groups. Based on these results, approximately 31% of aminopropyl groups at the silica surface have covalently bound C₆₀ functionalities, most of which likely reside at mesochannel surfaces nearby the silica particle surface because these regions are most accessible to solutions containing radical C₆₀ species during the postsynthetic attachment process. Interestingly, despite the partial yield of HC₆₀ attachment, incorporated HC₆₀ groups considerably influence the N₂ adsorption properties of SBA-15-APS-C₆₀H materials. For example, SBA-15-APS-C₆₀H materials have dramatically reduced average pore diameters relative to SBA-15-APS materials (Table 1). The adjusted average pore volume (modified to account for incorporated organosilica and HC species) of SBA-15-APS-C₆₀H materials (0.50 cm³ g⁻¹ silica) is reduced compared to mesoporous SBA-15 materials (0.78 cm³ g⁻¹ silica), which could reflect either an excluded volume effect from incorporated C₆₀ species or pore blockage by C₆₀ species. The adjusted BET surface areas of SBA-15-APS-C₆₀H materials (376 m² g⁻¹ silica support) are slightly lower than those of SBA-15-APS materials (433 m² g⁻¹ silica support). The high hydrophobicities and surface areas of mesoporous silica functionalized with C₆₀ species make these materials promising for the incorporation of large quantities of methylprednisolone species.

The methylprednisolone adsorption capacities of SBA-15, SBA-15-APS, and SBA-15-APS-C₆₀H materials are determined and shown to correlate qualitatively with the strengths of electrostatic interactions between methylprednisolone and the silica surfaces. Adsorption of methylprednisolone species was achieved by exposing mesoporous SBA-15, SBA-15-APS and SBA-15-APS-C₆₀H materials to aqueous solutions containing methylprednisolone at concentrations of 50 mg mL⁻¹. Subsequent elemental analyses establish methylprednisolone loadings (Table 1) of 93 mg g⁻¹ of mesoporous SBA-15 silica, and relatively greater loadings of 137 and 118 mg g⁻¹ of SBA-15-APS and SBA-15-APS-C₆₀H materials, respectively. Differences in methylprednisolone loadings among these materials can be explained by the electrostatic interactions among the methylprednisolone and silica surfaces. As the zeta potential of pure methylprednisolone sodium succinate is ~23 mV (measured at pH 7.4), these species will have stronger attractive electrostatic interactions with, and greater adsorption to, silica surfaces having greater positive charge. As expected, SBA-15-APS materials have the most positive zeta potential (6.58 mV at pH 7.4, Table 1) and greatest methylprednisolone adsorption capacity, while mesoporous SBA-15 silicas with the most negative zeta potential (~15.9 mV at pH 7.4) exhibit the lowest capacities. These results demonstrate that attractive electrostatic interactions are important, though not solely responsible...
for, methylprednisolone adsorption, as significant methylprednisolone adsorption is observed on surfaces that have negative surface charge and thus, on average, electrostatically repel methylprednisolone species (i.e., mesoporous SBA-15 silica). Therefore, attractive hydrogen-bonding and/or hydrophobic interactions also appear to influence methylprednisolone adsorption to silica surfaces.

Specific insights on intermolecular interactions between adsorbed methylprednisolone species and moieties at the functionalized mesoporous silica surfaces are provided by solid-state $^{13}$C and $^1$H NMR spectroscopy. For example, the solid-state 1D $^{13}$C-$^1$H CP-MAS NMR spectrum (Figure 1A) of SBA-15-APS-C$_{60}$H materials without methylprednisolone reveals well-resolved $^{13}$C signals associated with $^{13}$C moieties of the HC$_{60}$-aminopropyl groups. For example, the $^{13}$C signals at 10, 20, 34, 52, and 135−155 ppm are assigned to $^{13}$C moieties $a$, $b$, $c$, $d$, and those of the C$_{60}$ fullerene (blue dot), respectively. Importantly, the $^{13}$C-$^1$H CP-MAS NMR spectrum (Figure 1B) of materials with low methylprednisolone loadings yields $^{13}$C signals at 45, 70, 119, and 127 ppm (dotted red lines) that are not associated with $^{13}$C moieties of the HC$_{60}$-aminopropyl groups (or THAB impurities). These signals, and others, correspondingly increase in intensity (Figure 1C) for materials with higher methylprednisolone loadings, and are confidently assigned to the $^{13}$C moieties of the methylprednisolone species. The $^{13}$C signals associated with the alkyl moieties of the methylprednisolone guest have narrow line widths and reflect the relatively uniform $^{13}$C molecular environments of these $^{13}$C moieties for materials with both low and high methylprednisolone loadings, as shown in Figure 1B,C, respectively. A separate static (non-MAS) 1D $^{13}$C-$^1$H CP NMR spectrum of the sample with low methylprednisolone loading yields no resolved $^{13}$C signals, which are broadened beyond detection (Figure S3). Hence, the narrow $^{13}$C signals associated with the alkyl moieties of the methylprednisolone and HC$_{60}$-aminopropyl species can be concluded to result from relatively uniform MAS-averaged environments, rather than high molecular mobilities (relative to the 100 μs time scale of the NMR measurement). Interestingly, not all of the $^{13}$C signals associated with the methylprednisolone species are narrow, in particular those at 170−190 ppm from the carboxylic or ketone groups (1, 4, 6, and 16) in Figure 1C. These results suggest that the adsorption of the methylprednisolone guests occurs via hydrogen-bonding of carboxylate moieties to surface silanol sites, as depicted in the schematic diagram in Figure 1C. Combined with analysis of zeta potential data, these results indicate that methylprednisolone species adsorb to the silica surface of SBA-15-APS-C$_{60}$H materials based on electrostatic and hydrogen-bonding interactions.

While the solid-state 1D $^{13}$C-$^1$H CP-MAS NMR measurements yield molecular-level information about the HC$_{60}$-aminopropyl and methylprednisolone species, 2D $^{13}$C-$^1$H HETCOR measurements provide complementary insights on intermolecular interactions between these two species. Specifically, 2D $^{13}$C-$^1$H HETCOR measurements exploit through-space dipole–dipole couplings of locally proximate (<1 nm) $^{13}$C and $^1$H nuclei to correlate their isotropic chemical shifts. This provides direct information on intra- and intermolecular interactions among the chemically distinct $^{13}$C and $^1$H moieties of the HC$_{60}$-aminopropyl groups and methylprednisolone guests. In the 2D solid-state $^{13}$C-$^1$H HETCOR spectrum of Figure 2A, most of the observed intensity correlations are of intramolecular origin. These correlations corroborate the $^{13}$C and $^1$H signal assignments to specific moieties of the HC$_{60}$-aminopropyl group and methylprednisolone guest species, as labeled in the respective 1D single-pulse $^1$H MAS and $^{13}$C-$^1$H CP-MAS spectra in Figure 2A.

Intensity correlations in the solid-state 2D $^{13}$C-$^1$H HETCOR spectrum in Figure 2 also arise from intermolecular interactions between HC$_{60}$-aminopropyl and methylprednisolone species and provide evidence for preferential association of the methylprednisolone guests with the aminopropyl, as opposed to the HC$_{60}$ moieties. Despite many of the overlapping $^{13}$C signals of the HC$_{60}$-aminopropyl and methylprednisolone species, the $^{13}$C signal associated with the a (8−9 ppm) methylene moieties of the HC$_{60}$-aminopropyl group are well-resolved. Importantly, correlated $^{13}$C signals (8−9 ppm) associated with the a groups of the HC$_{60}$-aminopropyl moieties and $^1$H signals (1.9−2.6 ppm, red shading) from the methylprednisolone alkyl moieties establishes the mutual interactions among HC$_{60}$-aminopropyl groups and methylprednisolone guests. Although intensity correlations associated with the $^{13}$C signals of the alkyl moieties (<80 ppm) are observed, the 2D $^{13}$C-$^1$H HETCOR spectrum yields no correlated intensities in the $^{13}$C region 140−148 ppm (not shown in Figure 2A) associated with the $^{13}$C signals of the HC$_{60}$ moieties. This may reflect relatively weak hydrophobic or π−π interactions between methylprednisolone guests and the adsorbed methylprednisolone species.
HC$_{60}$ moieties, or a relatively broad distribution of local interaction environments with the C$_{60}$ fullerene. Due to the many overlapping $^{13}$C signals of the HC$_{60}$-aminopropyl group and methylprednisolone guest in this 2D $^{13}$C($^1$H) HETCOR spectrum (Figure 2A) a specific configuration of the interacting methylprednisolone guest cannot be inferred and likely reflects a distribution of methylprednisolone configurations. Analysis of the 2D $^{13}$C($^1$H) HETCOR spectrum (Figure 2A) establishes the close (<1 nm) molecular proximities of HC$_{60}$-aminopropyl groups and methylprednisolone guests, providing direct evidence for intermolecular interactions among the aminopropyl groups and methylprednisolone alkyl moieties, as depicted in the schematic diagram in Figure 2B. We hypothesize that such interactions influence the release properties of methylprednisolone molecular guests.

The fractions and rates of methylprednisolone released from SBA-15, SBA-15-APS and SBA-15-APS-C$_{60}$H materials into simulated body fluids are quantified and analyzed to understand how surface aminopropyl and C$_{60}$ moieties influence the release behaviors of methylprednisolone species. The amounts of methylprednisolone species released from mesoporous silica hosts into simulated body fluids under near neutral conditions (pH 7.4), corresponding to those in the bloodstream, can be estimated by using UV–visible spectroscopy to measure the absorbance intensity at 248 nm, which is associated with methylprednisolone molecules. Specifically, the quantities of methylprednisolone released from mesoporous SBA-15, SBA-15-APS, or SBA-15-APS-C$_{60}$H silica materials were determined by applying the Beer–Lambert law to the absorbance intensities at 248 nm in UV–visible spectra acquired for simulated body fluids that were exposed for various time periods to these mesoporous silica host materials. Normalizing the amounts of released methylprednisolone species to the initial mass of methylprednisolone contained in the mesoporous SBA-15, SBA-15-APS, or SBA-15-APS-C$_{60}$H silica material yields the cumulative fractions of methylprednisolone released from these materials, as depicted in Figure 3A. After exposure to simulated body fluids, large fractions of the methylprednisolone species were released from all three of the mesoporous silica materials at times <500 min (Figure 3A). At times >500 min, the fractions of methylprednisolone released from these mesoporous hosts approach constant values that are lower than 100%, indicating incomplete extents of methylprednisolone release, due to diffusion resistances or sorption equilibrium of methylprednisolone species with the mesoporous silica surfaces. In particular, similar fractions of methylprednisolone (~80–90%) were released from mesoporous SBA-15, SBA-15-APS, and SBA-15-APS-C$_{60}$H silica materials, indicating that surface aminopropyl and C$_{60}$ groups do not significantly influence the fractions of methylprednisolone released from functionalized mesoporous silica materials. However, methylprednisolone species were observed to release from the nonfunctionalized and functionalized mesoporous silica hosts at significantly different rates (Figure 3B), which were determined from the derivative of the cumulative methylprednisolone release profiles (Figure S5) at specific points in time. For example, higher rates of methylprednisolone release were observed for aminopropyl-functionalized SBA-15-APS materials, compared to nonfunctionalized mesoporous SBA-15 silica materials, which arise in part from the higher loadings of methylprednisolone in the former (137 mg g$^{-1}$ material versus 93 mg g$^{-1}$ material). More specifically, materials with higher methylprednisolone loadings are expected to have larger release rates because of the increased prevalence of relatively weak drug–drug intermolecular interactions, versus stronger drug-host interactions, that facilitates methylprednisolone release into simulated body fluid. Additionally, the high loadings of methylprednisolone species yield large concentration gradients for the transport of methylprednisolone from the host to simulated body fluid, which likely contribute to the large release rates. Importantly, Figure 3B also shows lower methylprednisolone release rates from SBA-15-APS-C$_{60}$H materials than from nonfunctionalized SBA-15 silica, despite the higher methylprednisolone loadings for the C$_{60}$-functionalized materials (118 mg g$^{-1}$ material), compared to non-functionalized mesoporous SBA-15 silica (93 mg g$^{-1}$ material). These results establish that the release of methylprednisolone species from mesoporous silica materials is mediated by surface-grafted C$_{60}$ moieties, presumably due to steric effects that are also evidenced by the significantly reduced pore diameters (Table 1) for SBA-15-APS-C$_{60}$H sterics relative to SBA-15 and SBA-15-APS silica materials. The high hydrophobicities of C$_{60}$ species may also inhibit the influx of aqueous simulated body fluids into mesoporous SBA-15-APS-C$_{60}$H materials, thereby reducing methylprednisolone transport within the mesochannels.

The methylprednisolone release from the aminopropyl-functionalized mesoporous SBA-15-APS and SBA-15-APS-C$_{60}$H silica materials into simulated body fluids can be described by using first-order and Korsmeyer-Peppas kinetic models. The first-order kinetic model for drug release assumes that the rate of methylprednisolone release from a mesoporous...
silica host material is proportional to the concentration of pharmaceuticals in the simulated body fluid. Smaller first-order rate coefficients (the constants of proportionality) correspond to lower release rates of methylprednisolone from the mesoporous silica hosts. Analyses of the cumulative methylprednisolone release profiles (Figure S5) using the first-order kinetic model reveal that the lowest first-order rate coefficients (0.0072 min\(^{-1}\)) are associated with the SBA-15-APS-C\(_{60}\) materials, compared to nonfunctionalized mesoporous SBA-15 (0.0080 min\(^{-1}\)) and SBA-15-APS silica (0.0201 min\(^{-1}\)). These relative values are consistent with mediated transport of methylprednisolone within the mesochannels by C\(_{60}\) moieties grafted to the silica surface. By comparison, the Korsmeyer–Peppas kinetic model for drug release provides complementary insight about the diffusion of methylprednisolone molecules within mesoporous silica materials, in particular whether diffusion occurs by Fickian or non-Fickian processes. Cumulative methylprednisolone release profiles associated with SBA-15-APS and SBA-15-APS-C\(_{60}\) materials are fitted well by the Korsmeyer-Peppas model, according to the \(R^2\) values listed in Table S2. Assuming spherical particle geometries for the SBA-15-APS and SBA-15-APS-C\(_{60}\) materials, the Korsmeyer-Peppas fitting analyses suggest non-Fickian diffusion for methylprednisolone molecules within these functionalized mesoporous materials, within the standard errors associated with the analyses. Such diffusion processes are consistent with the impeded diffusion of methylprednisolone within functionalized mesoporous materials by the nanoscale pore dimensions and/or the interactions among methylprednisolone and moieties at the silica surfaces.

As functionalities at the silica surface of mesoporous silicas can significantly influence methylprednisolone adsorption and release behaviors, materials grafted with either aminobutyl organosilica species were evaluated as hosts for methylprednisolone delivery. The amounts of aminobutyl and aminobutyl-C\(_{60}\) organosilica species grafted to SBA-15-ABS and SBA-15-ABS-C\(_{60}\) materials, respectively, were similar to those for SBA-15 materials functionalized with aminopropyl organosilica species. The adsorption and release behaviors of methylprednisolone in aminobutyl-functionalized SBA-15-ABS and SBA-15-ABS-C\(_{60}\) materials into simulated body fluid (pH 7.4) were quantified and can be explained by the intramolecular interactions among methylprednisolone and moieties at the functionalized mesoporous silica surfaces. The capacities for methylprednisolone adsorption were lower for SBA-15-ABS-C\(_{60}\) materials (82 mg g\(^{-1}\) sample), than for SBA-15-ABS materials (117 mg g\(^{-1}\) sample), which are consistent with stronger attractive electrostatic interactions between methylprednisolone and the silica surfaces of SBA-15-ABS materials as established by the zeta potential values (Table 1) of the respective materials. Exposure of methylprednisolone-loaded mesoporous SBA-15-ABS or SBA-15-ABS-C\(_{60}\) silica materials to simulated body fluids resulted in incomplete release of methylprednisolone species, again likely due to diffusion limitations or sorption equilibrium of methylprednisolone with the functionalized silica surfaces. Interestingly, approximately 90% of methylprednisolone was released from nonfunctionalized mesoporous SBA-15 silica materials, while lower fractions of 75% and 50% were released from mesoporous SBA-15-ABS and SBA-15-ABS-C\(_{60}\) silica materials, respectively. The instantaneous rates of methylprednisolone release (Figure 4B) from the mesoporous SBA-15-ABS and SBA-15-ABS-C\(_{60}\) silica materials were lower than from nonfunctionalized mesoporous SBA-15 silica, despite the greater loadings of methylprednisolone for the functionalized mesoporous silica materials. These results establish that the release of methylprednisolone species from the mesoporous SBA-15-ABS and SBA-15-ABS-C\(_{60}\) silica materials can be mediated by the grafted aminobutyl and C\(_{60}\) moieties at the mesoporous surface. Moreover, analyses of the instantaneous release profiles (Figure S3) of SBA-15-ABS and SBA-15-ABS-C\(_{60}\) materials using a first-order kinetic release model yields first-order rate coefficients of 0.0034 and 0.0045 min\(^{-1}\), respectively. These rate coefficients are lower than those associated with nonfunctionalized mesoporous SBA-15 silica (0.0080 min\(^{-1}\)), establishing the slower release of methylprednisolone from the mesoporous silica materials with aminobutyl and/or C\(_{60}\) surface functionalities. Using the Korsmeyer-Peppas kinetic model as previously described indicates that methylprednisolone molecules diffuse by a non-Fickian process in SBA-15-ABS and SBA-15-ABS-C\(_{60}\) materials, just as in the case of aminopropyl functionalized mesoporous silica.

Notable differences in the release behaviors of methylprednisolone species from aminopropyl-functionalized SBA-15-APS-C\(_{60}\) and aminobutyl-functionalized SBA-15-ABS-C\(_{60}\) materials into simulated body fluids (pH 7.4) are observed despite the similar quantities of grafted amino organosilica and HC\(_{60}\) species in these two materials. For example, the fractions of methylprednisolone released from SBA-15-APS-C\(_{60}\) and SBA-15-ABS-C\(_{60}\) materials were 90% and 50%, respectively, as shown in Figure 5A. The relatively low fractions of
methylprednisolone released from mesoporous SBA-15-ABS-C_{60}H silica materials correlate with the lower methylprednisolone loadings in SBA-15-ABS-C_{60}H materials (82 mg g\(^{-1}\) material), compared to SBA-15-APS-C_{60}H materials (118 mg g\(^{-1}\) material), and may be influenced also by stronger interactions of methylprednisolone species with the more hydrophobic aminobutyl versus aminopropyl surface moieties. Additionally, as shown in Figure 5B, lower rates of methylprednisolone release were observed from mesoporous SBA-15-ABS-C_{60}H, compared to SBA-15-APS-C_{60}H silica materials, which reflects in part the greater methylprednisolone loadings in SBA-15-APS-C_{60}H materials. However, analyses of the cumulative profiles of methylprednisolone release (Figure S3) for the C_{60}-functionalized mesoporous materials using a first-order kinetic release model yields lower first-order rate coefficients associated with the SBA-15-ABS-C_{60}H materials (0.0045 min\(^{-1}\)) than for the SBA-15-APS-C_{60}H materials (0.0072 min\(^{-1}\)), as shown in Table S2.

The slower release of methylprednisolone from mesoporous silicas that have aminobutyl-C_{60}H, versus aminopropyl-C_{60}H, surface moieties may be due to differences in their respective steric, hydrogen-bonding or electrostatic interactions, or methylprednisolone loadings. Based on the modestly different lengths of the alkyl chains of aminopropyl and aminobutyl surface moieties, it is expected that SBA-15-APS-C_{60}H and SBA-15-ABS-C_{60}H materials will result in similar steric impediments to methylprednisolone diffusion within mesopores; such similarities are consistent with the identical mean BET pore diameters (4.4 ± 0.6 nm, Table 1) of both materials and with recent molecular simulations and analyses by Doadrio et al. on the release of dye species from similarly functionalized mesoporous silicas. Both C_{60}-functionalized materials also have similar quantities of aminalkyl surface functionalities and so are expected to exhibit similar extents of hydrogen-bonding interactions with methylprednisolone species. By comparison, the lower zeta potential values (Table 1) associated with SBA-15-ABS-C_{60}H, compared to SBA-15-APS-C_{60}H, materials indicate that the former manifest weaker electrostatic interactions with methylprednisolone guests. However, if predominant, such weaker interactions would be expected to lead to faster rates of release for SBA-15-ABS-C_{60}H materials, which is opposite to what is observed for the macroscopic release data. The lower release rates observed for SBA-15-ABS-C_{60}H materials are consistent with the relatively lower methylprednisolone loadings of SBA-15-ABS-C_{60}H (82 mg drug/sample) versus those of SBA-15-APS-C_{60}H (118 mg drug/g sample) materials, which impart smaller concentration gradients to drive diffusion and release from the host materials.

Exposure of C_{60}-functionalized mesoporous silica materials to simulated body fluids under acidic conditions (pH 4.6), corresponding to those nearby tumors, yields lower fractions and rates of methylprednisolone release compared to under near neutral conditions (pH 7.4). For example, while approximately 85% of the total methylprednisolone species were released from SBA-15-APS-C_{60}H materials under near neutral conditions, lower fractions of ~70% were released from identical materials under acidic conditions, as shown in Figure 5A. Similarly reduced fractions of methylprednisolone were released from SBA-15-ABS-C_{60}H materials under acidic conditions. The lower fractions of methylprednisolone released from these C_{60}-functionalized silica materials are consistent with the increased attractive electrostatic interactions among methylprednisolone and the functionalized silica surfaces under acidic versus near neutral conditions, as evidenced by the zeta potential measurements (Table 1) of the corresponding materials. Similarly, the reduced rates of methylprednisolone release from SBA-15-APS-C_{60}H and SBA-15-ABS-C_{60}H materials under acidic conditions, as shown in Figure 5B, are also consistent with the increased attractive electrostatic interactions. Analyses of methylprednisolone release profiles into acidic simulated body (Figure S5C) using the Korsmeyer-Peppas kinetic model reveal similar non-Fickian diffusion processes for methylprednisolone in both SBA-15-APS-C_{60}H and SBA-15-ABS-C_{60}H materials, as observed under near neutral conditions. The reduced rates of methylprednisolone release from C_{60}-functionalized materials under acidic conditions would promote longer durations of pharmaceutical release from these materials in the vicinity of tumors. Therefore, if used for tumor treatment, the C_{60}-functionalized materials could allow the pharmaceutical to be administered less frequently to patients, which could subsequently improve patient compliance.

**CONCLUSIONS**

The molecular-level interactions among a representative pharmaceutical species, methylprednisolone sodium succinate, and moieties on the interior surfaces of mesoporous SBA-15 silica materials were established and correlated with bulk adsorption properties. Specifically, mesoporous SBA-15 silica...
materials with aminopropyl or aminobutyl surface moieties and with C₆₀ species were characterized and evaluated for the adsorption of methylprednisolone species. Methylprednisolone adsorption to these materials was shown to depend strongly on the electrostatic interactions among methylprednisolone molecules and the functionalized silica surfaces, which correlate with the different loadings for the functionalized materials. Complementary solid-state 1D $^{13}$C{$^1$}H CP-MAS NMR measurements provided evidence for hydrogen-bonding between methylprednisolone species and the silica surface, while 2D $^{13}$C{$^1$}H HETCOR NMR techniques established the close molecular proximities of the alkyl moieties of methylprednisolone species and aminopropyl functionalities at the silica surface, suggesting attractive hydrophobic interactions among these species. These results indicate that the adsorption of methylprednisolone to SBA-15 materials functionalized with H$_2$C$_6$O$_y$-amino organosilica species involves contributions from electrostatic, hydrophobic-bonding, and hydrophobic interactions.

The transient release of methylprednisolone from functionalized mesoporous SBA-15 silica materials into simulated body fluids was monitored to understand the influence of the different surface functionalities on methylprednisolone release behaviors. The surface-grafted aminopropyl, aminobutyl, and C$_6$O$_y$ surface moieties of functionalized mesoporous silica materials appear to reduce the rates of methylprednisolone release by a combination of electrostatic, hydrophobic and steric effects. Indeed, C$_6$O$_y$-functionalized SBA-15-APS-C$_6$O$_y$H and SBA-15-ABS-C$_6$O$_y$H materials showed the slowest methylprednisolone release rates of all materials investigated. Methylprednisolone release from these functionalized mesoporous silica materials was evaluated under acidic and near neutral pH conditions, which correspond to conditions nearby tumors and in the bloodstream, respectively. Lower fractions and rates of methylprednisolone release were observed from C$_6$O$_y$-functionalized mesoporous silica materials under acidic conditions (pH 4.6) versus near neutral conditions (pH 7.4), which were attributed to stronger electrostatic interactions among methylprednisolone and the surfaces of the C$_6$O$_y$-functionalized SBA-15 silica. These results demonstrate that the types of surface-grafted alkylamino and C$_6$O$_y$ functionalities can mediate pharmaceutical release from functionalized mesoporous silica materials. The detailed understanding of molecular-level properties and interactions of methylprednisolone and C$_6$O$_y$-functionalized mesoporous silica developed here provides important information for designing effective silica-based drug-delivery systems.

Figure S1. Solid-state 1D single-pulse $^{29}$Si MAS NMR spectra of (a) SBA-15-APS, (b) SBA-15-ABS, and (c) SBA-15-APhS materials. Signals in a 1D single-pulse $^{29}$Si NMR spectrum arise from chemically distinct $^{29}$Si species and are resolved based on chemical shift, while their integrated areas reflect the quantities of each $^{29}$Si species. Three distinct signals are observed at -110 and -102 ppm which are assigned to $Q^4$ and $Q^3$ $^{29}$Si species, while the signals at ca. -65 ppm correspond to $T^1$, $T^2$, and $T^3$ $^{29}$Si associated with amino organosilica species. The quantities of amino organosilica loadings are ascertained by comparing the integrated areas of signals from $T$ and $Q$ species reveal organosilica loadings (Table S1).
Figure S2. Thermogravimetric analyses plots of (A) SBA-15-NH$_2$ materials (B) SBA-15-NH-C$_{60}$H materials. The TGA plots of SBA-15-NH$_2$ materials (A) show mass losses between temperatures of 120 ºC and 700 ºC that are solely attributable to the decomposition of the organic moieties of amino organosilica species, and thus enable organosilica loadings to be quantified (Table S1). Additional mass losses are observed in the TGA plots of SBA-15-NH-C$_{60}$H materials (B) at temperatures of approximately 500 ºC, which are associated to the decomposition of fullerene C$_{60}$ species. A comparison of mass losses between appropriate SBA-15-NH and SBA-15-NH-C$_{60}$H materials allows incorporated C$_{60}$ species to be quantified (Table S1). In all TGA plots, mass losses between temperatures of 40 ºC and 120 ºC are attributed to the removal of adsorbed water.
Figure S3. Solid-state 1D $^{13}$C CP-MAS spectra of mesoporous SBA-15 silica functionalized with HCD$_{60}$-aminopropyl groups with 15 mg mL$^{-1}$ loadings of methylprednisolone guest species taken under (a) 8 kHz MAS and (b) static (non-spinning) conditions mg mL$^{-1}$. The spectra were all acquired at room temperature with a 2 ms CP contact time.
Figure S4. Solid-state 1D $^{13}$C{$^1$H} CP-MAS NMR spectra of (A) SBA-15-ABS-C$_{60}$H and (B) SBA-15-APhS-C$_{60}$H materials. In A, $^{13}$C signals at 11, 21, 29 and 57 ppm are assignable to $^{13}$C species 1, 2, 3 and 4 of the aliphatic aminobutyl chains, while signals at ca. 145 ppm are attributable to the aromatic $^{13}$C species of the C$_{60}$ fullerene moieties. In B, the $^{13}$C signals at 134 ppm are assignable to the aromatic $^{13}$C groups 1 and 2, while signals at 112 and 146 ppm are associated with $^{13}$C species 3 and 4, of the aminophenyl moieties of grafted aminophenyl organosilica species. Additionally, in B, the $^{13}$C signals at ca. 145 ppm are associated with the HC$_{60}$ moieties and overlap with signals associated with species 4 of the aminophenyl moieties. Both spectra were acquired at room temperature under MAS conditions of 6 kHz with CP contact times of 1 ms.
Figure S5. The cumulative profiles of methylprednisolone released into simulated body fluid (pH=7.4, 37 °C) as a percent of the methylprednisolone adsorption capacity for a given material are plotted versus time for (A) SBA-15-APS (pink, squares) and SBA-15-APS-C$_{60}$H (blue, triangles) materials, and (B) SBA-15-ABS (pink, squares) and SBA-15-ABS-C$_{60}$H (blue, triangles). In (C), the extents of methylprednisolone released for SBA-15-APS-C$_{60}$H materials into simulated body fluids at pH 7.4 (red, circles) and pH 4.6 (orange, squares), and from SBA-15-ABS-C$_{60}$H into simulated body fluids at pH 7.4 (blue, triangles) and pH 4.6 (pink, stars) are plotted versus time. Simulated body fluid under approximately neutral conditions (pH 7.4) was a PBS buffered solution, while simulated body fluid under acidic conditions (pH 4.6) was an acetate buffered solution.
